Growing high-quality grasses for dairy rations requires attention to detail

As interest grows in adding grasses to dairy rations (to add digestible fiber and improve cow performance and health), many dairy producers find themselves learning about a feedstuff they haven't grown or used in many years. This Fact Sheet will explore some reasons for feeding grasses, discuss some of the agronomic considerations producers need to think about when growing grasses for dairy rations, and consider some differences between growing alfalfa versus grasses. It is not about grazing, or growing grasses in mixture with alfalfa, or harvesting whatever is growing on the Back 40 as an emergency source of forage; it is about growing grasses as an intentional source of high quality forage for dairy rations.

Nutritional reasons for feeding grass

From a ration perspective, grasses are an effective source of fiber (measured as NDF) and also a fiber that is highly digestible (measured as NDFD). Grasses also have a positive effect on milk fat. With today's high-producing dairy cows being fed a high proportion of grain, producers must be extra cautious about feeding adequate fiber. David Combs, an extension dairy scientist at the University of Wisconsin-Madison, lists the following reasons for adding some grass into dairy rations:

- A TMR mixture of grass and legumes has more total fiber compared to alfalfa alone.
- Grass has a higher proportion of digestible fiber

than either alfalfa or corn silage alone.

- Grass can be a good fit with corn silage, which is lower in fiber and is high in non-fiber carbohydrates (the grain portion).

But because grasses increase the fiber content of a ration, they will also slow the passage of feed through the cow. If all other ration components remain the same, this will also reduce intake. Research has shown that grass-based diets have little negative effect on cows that have lower nutrient demand, such as late-lactation cows, dry cows, and heifers. But

adding grass can reduce milk production when cows are at peak lactation because of the reduction in feed intake.

Growing grasses

From an agronomic perspective, advantages of growing grasses include: grasses are adapted to a wide range of soils; there are fewer problems with pests and winterkill with grasses compared to alfalfa; grasses dry faster than alfalfa; grasses are highly responsive to nitrogen; and, for dairy producers growing their own feed, grass fields provide an additional option for applying manure and managing manure nutrients.

Grass seed and varieties should be chosen with as much care as corn and alfalfa. Don't just plant whatever the feed mill has in stock; choose seed with a named variety as opposed to "variety not stated" on

the label in order to take advantage of genetic improvements. Choose varieties with medium to late maturity for maximum flexibility in scheduling harvest and with rust resistance to avoid forage quality and palatability problems.

One good source for comparing grass varieties is the University of Wisconsin Team Forage web site at <http://fyi.uwex.edu/forage/> (select “Forage Species,” then “Grasses”). Another good source is Cornell University, <http://www.forag-es.org/> (select the “Forage Species Selector”). Many states with a forage extension program will have local variety-trial information available on the web.

To attain successful establishment in a new grass field, first follow the seeding rates recommended by a local university. More persistent grass may be sown with less persistent grass for faster cover and improved seeding year yield. For example, seed tall fes-

cue or orchardgrass @ 10 lb/acre with Italian ryegrass or Festulolium @ 2 lb/acre. Seed in the spring (April to May) or summer (July to August) into a firm, well-prepared seedbed at a depth of ¼ to ¾ inches, depending on seed size. Apply 30-40 lb nitrogen/acre when seedlings are 4-6 inches tall. Control broadleaf weeds with herbicides and annual grass weeds by frequent clipping in the establishment year.

Alfalfa fixes its own nitrogen, but grasses need some help via fertilizer and/or manure. Applications made in early spring, before and after the first harvest, have the greatest impact on yield due to seasonal growth patterns. As shown in Figure 1, the annual yield of grass continues to climb as more and more nitrogen is applied. Figure 2, however, shows that the efficiency of yield production, or the pounds of dry matter produced per pound of nitrogen applied, declines after the annual nitrogen rate exceeds 120 to 150 pounds nitrogen per acre per year.

Figure 1. Response of orchardgrass, tall fescue, and meadow fescue to nitrogen application rate at two locations. Brink et. al., 2010.

Figure 2. Efficiency of yield production, or pounds dry matter/pound of nitrogen applied, at various application rates. Brink et. al., 2010.

One of the biggest advantages of growing grasses on a dairy farm is that it opens a new window of opportunity for spreading manure. Manure application on corn and other annual crops is generally limited to early spring before planting or in the fall after harvest. But with a grass forage crop, manure can be applied in early spring and after each harvest through the summer. Because of the high nitrogen need of forage grasses, there can be large yield increases from manure application. And because of the year-round vegetation and fibrous root system of grasses, there is less potential for nitrate leaching than with corn.

As with any surface broadcast application, there can be large losses of nitrogen to the air as ammonia. To minimize these losses, avoid applying under warm, windy conditions. Even better, equipment is now available to band-apply or partially incorporate liquid manure, which reduces volatile losses of nitrogen.

Whether fertilizer or manure is used as the nitrogen source, use a split application, with no more than 60 pounds nitrogen per acre in each application, to improve the utilization efficiency by the crop and the cows; excess nitrogen fertilizer leads to more protein in the crop and consequently more nitrogen excreted in the manure.

Watch potassium levels

As beef cow-calf operators well know, a high potassium concentration in grasses can cause problems with cows after freshening. High dietary potassium levels raise the blood pH, which interferes with calcium absorption from feed and mobilization from bones. This can lead to milk fever (hypocalcemia, or low blood calcium). To reduce the risk of milk fever, stop feeding high-potassium grasses three weeks prior to

calving; orchardgrass and perennial ryegrass have the highest levels of potassium.

Ways to manage grasses to reduce their potassium concentration include: grow on low- to medium-potassium soils, if possible; feed first cutting to heifers and dry cows because the potassium concentration is highest in the spring; and apply manure in the summer or fall when potassium content of the grass is lower.

For dairy-quality forage, harvest grass at the boot stage, shown here.

Harvest and storage

Timing of harvest is a major consideration in the spring. The quality of grass is higher in the spring but declines more rapidly, compared to alfalfa (Figures 3 and 4) and also when compared to subsequent grass cuttings when the quality is lower but declines more slowly (Figure 5 on back). Therefore, timing of the first cutting is more critical whereas timing of summer and fall cuttings can be delayed a bit if needed.

When harvesting grass for hay or silage, cutting height is a major consideration. A closer cut means a higher yield. In one study conducted for two years (3 harvests/year) at both Marshfield and Lancaster, WI,

average yield for grass hay cut with a 2-inch stubble was 6,900 pounds/acre/year while the fields cut with a 4-inch stubble yielded 5,400 pounds/acre/year. However, a shorter cutting height led to a less persistent stand (see pictures on back). If stand persistence is important, leave an adequate stubble height of about 4 inches. If the grass will be rotated in two or three years, don't worry about stubble height.

Figure 3. Neutral Detergent Fiber (NDF) of alfalfa and grass at various stages of maturity. Brink & Casler, 2005; Brink et al., 2010.

Figure 4. Neutral Detergent Fiber Digestibility (NDFD) of alfalfa and grass at various stages of maturity. Brink & Casler, 2005; Brink et al., 2010.

When ensiling, grasses should be put up at 60 to 65% moisture if going into a bag, bunker or pile silo. Moisture content should be between 50 and 60% for tower silos. If you are making wrapped bale silage, moisture should be less than 60%. Remember that grasses dry faster than alfalfa, so monitor the moisture closely. And don't judge just by the feel; a "soft" feel does not mean that it's wet (as it does with alfalfa). Compaction is critical to making both grass silage and alfalfa silage. However, at a given moisture using the same packing practices, the density of grass silage is generally less than alfalfa silage, so pay particular attention to packing. Silage inoculants have been shown to be beneficial with grass silage, improving dry matter recovery and animal performance, but they are not a substitute for good management.

Summary

Decide how producing grass fits into your farm management and how feeding grass forage fits into your herd's ration. Grow and manage grasses as carefully as you would alfalfa. Attention to detail during establishment and harvest results in productive stands having the potential to provide high quality forage appropriate for dairy diets.

Figure 5: Change in forage nutritive value of temperate grasses.

Forage quality declines more rapidly early in the season, or with first cutting, as the fiber content increases (NDF) more rapidly and the digestibility quickly decreases (NDFD).
